Thread-Level Parallelism

- Goal: connecting multiple computers to get higher performance
  - Multiprocessors
  - Scalability, availability, power efficiency
- Task-level (process-level) parallelism
  - High throughput for independent jobs
- Parallel processing program
  - Single program run on multiple processors
- Multicore microprocessors
  - Chips with multiple processors (cores)

Parallel Programming

- Parallel software is the problem
- Need to get significant performance improvement
  - Otherwise, just use a faster uniprocessor, since it's easier!
- Difficulties
  - Partitioning
  - Coordination
  - Communications overhead

Threads in Conventional Processor

- One thread runs at once
- When one thread stalls (for example, waiting for memory):
  - Architectural state of that thread stored
  - Architectural state of waiting thread loaded into processor and it runs
  - Called context switching
- Appears to user like all threads running simultaneously

Multithreading

- Multiple copies of architectural state
- Multiple threads active at once:
  - When one thread stalls, another runs immediately
  - If one thread can't keep all execution units busy, another thread can use them
- Does not increase instruction-level parallelism (ILP) of single thread, but increases throughput

Intel calls this "hyperthreading"

Multiprocessors

- Multiple processors (cores) with a method of communication between them
- Types:
  - Homogeneous: multiple cores with shared memory
  - Heterogeneous: separate cores for different tasks (for example, DSP and CPU in cell phone)
  - Clusters: each core has own memory system

Amdahl's Law

$$T_{improved} = \frac{T_{affected}}{improvement\ factor} + T_{unaffected}$$

- Sequential part can limit speedup
- Example: 100 processors, 90 × speedup?
  - $T_{new} = T_{parallelizable}/100 + T_{sequential}$
  - Speedup = $\frac{1}{(1 - F_{parallelizable}) + F_{parallelizable}/100} = 90$
  - Solving: $F_{parallelizable} = 0.999$
- Need sequential part to be 0.1% of original time

Scaling Example 1

- Workload: sum of 10 scalars, and 10 × 10 matrix sum
  - Speed up from 10 to 100 processors
- Single processor: Time = (10 + 100) × t_{add}
- 10 processors
  - Time = 10 × t_{add} + 100/10 × t_{add} = 20 × t_{add}
  - Speedup = 110/20 = 5.5 (55% of potential)
- 100 processors
  - Time = 10 × t_{add} + 100/100 × t_{add} = 11 × t_{add}
  - Speedup = 110/11 = 10 (10% of potential)
- Assumes load can be balanced across processors

Scaling Example 2

- What if matrix size is 100 × 100?
- Single processor: Time = (10 + 10000) × t_{add}
- 10 processors
  - Time = 10 × t_{add} + 10000/10 × t_{add} = 1010 × t_{add}
  - Speedup = 10010/1010 = 9.9 (99% of potential)
- 100 processors
  - Time = 10 × t_{add} + 10000/100 × t_{add} = 110 × t_{add}
  - Speedup = 10010/110 = 91 (91% of potential)
- Assuming load balanced

Strong vs Weak Scaling

- Strong scaling: problem size fixed
  - As in example
- Weak scaling: problem size proportional to number of processors
  - 10 processors, 10 × 10 matrix
    - Time = $20 \times t_{add}$
  - 100 processors, 32 × 32 matrix
    - Time = $10 \times t_{add} + 1000/100 \times t_{add} = 20 \times t_{add}$
  - Constant performance in this example

Threading: Definitions

- Process: program running on a computer
  - Multiple processes can run at once: e.g., surfing Web, playing music, writing a paper
- Thread: part of a program
  - Each process has multiple threads: e.g., a word processor may have threads for typing, spell checking, printing

Multithreading

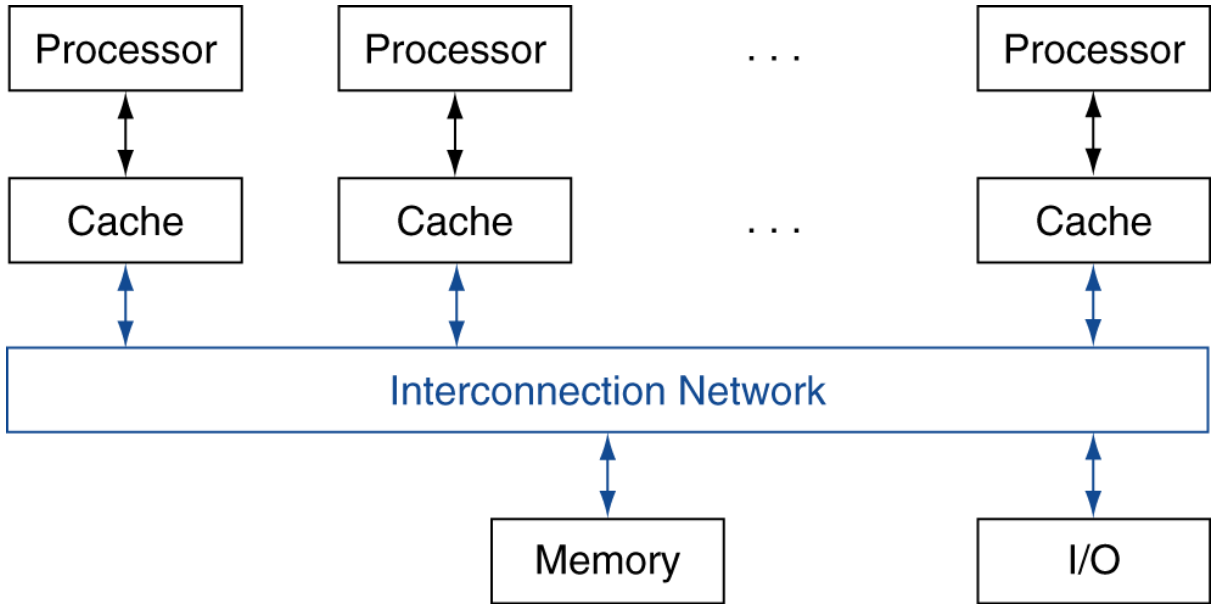
- Performing multiple threads of execution in parallel
  - Replicate registers, PC, etc.
  - Fast switching between threads
- Fine-grain multithreading
  - Switch threads after each cycle
  - Interleave instruction execution
  - If one thread stalls, others are executed
- Coarse-grain multithreading
  - Only switch on long stall (e.g., L2-cache miss)
  - Simplifies hardware, but doesn’t hide short stalls (eg, data hazards)

Simultaneous Multithreading

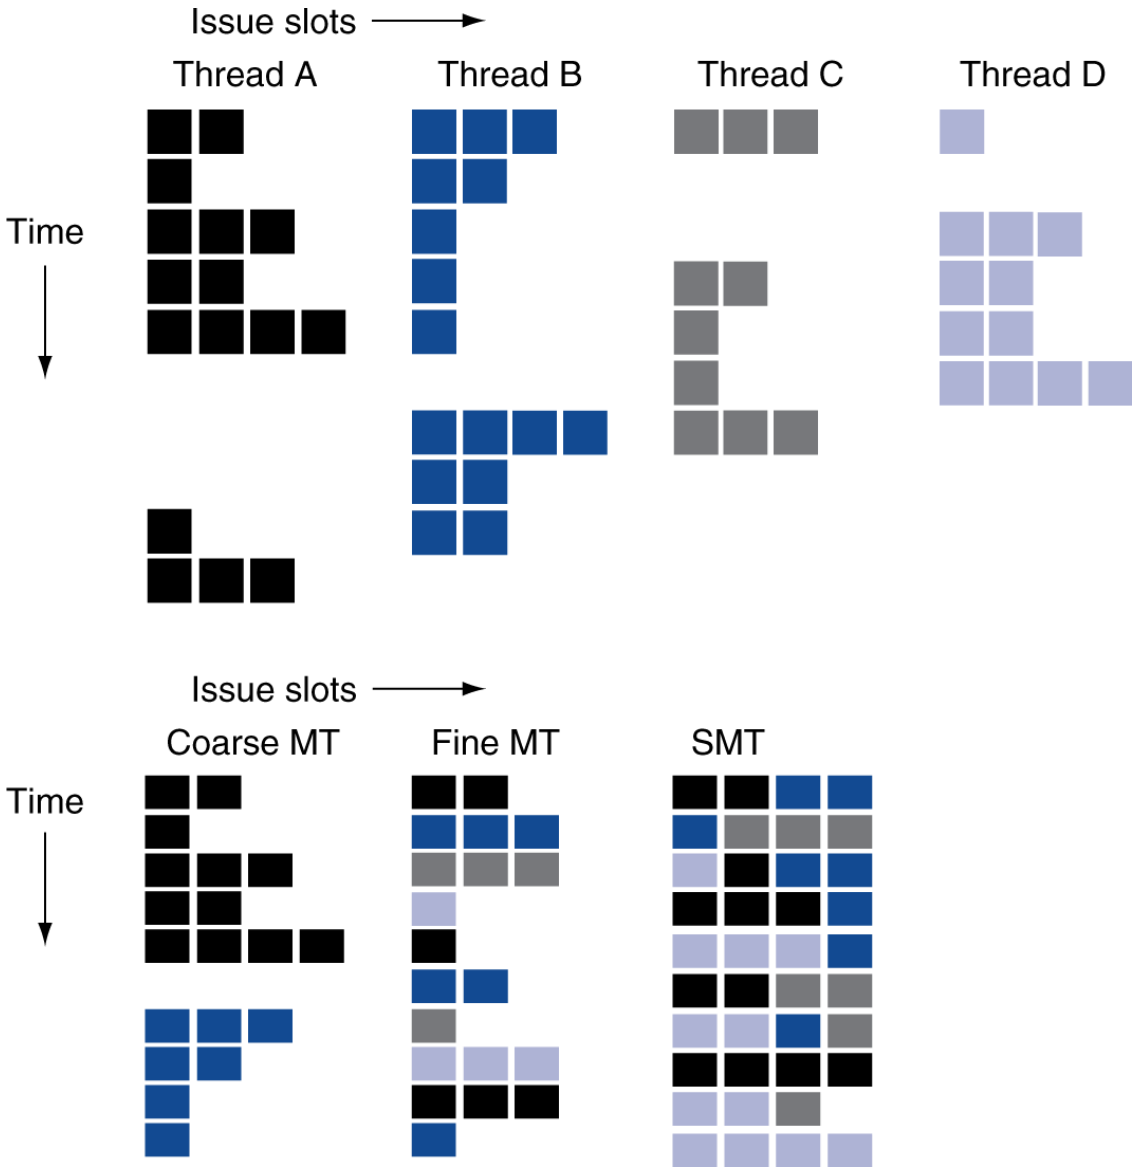
- In multiple-issue dynamically scheduled processor
  - Schedule instructions from multiple threads
  - Instructions from independent threads execute when function units are available
  - Within threads, dependencies handled by scheduling and register renaming
- Example: Intel Pentium-4 HT
  - Two threads: duplicated registers, shared function units and caches

Shared Memory

- SMP: shared memory multiprocessor
  - Hardware provides single physical address space for all processors
  - Synchronize shared variables using locks
  - Memory access time
    - UMA (uniform) vs. NUMA (nonuniform)

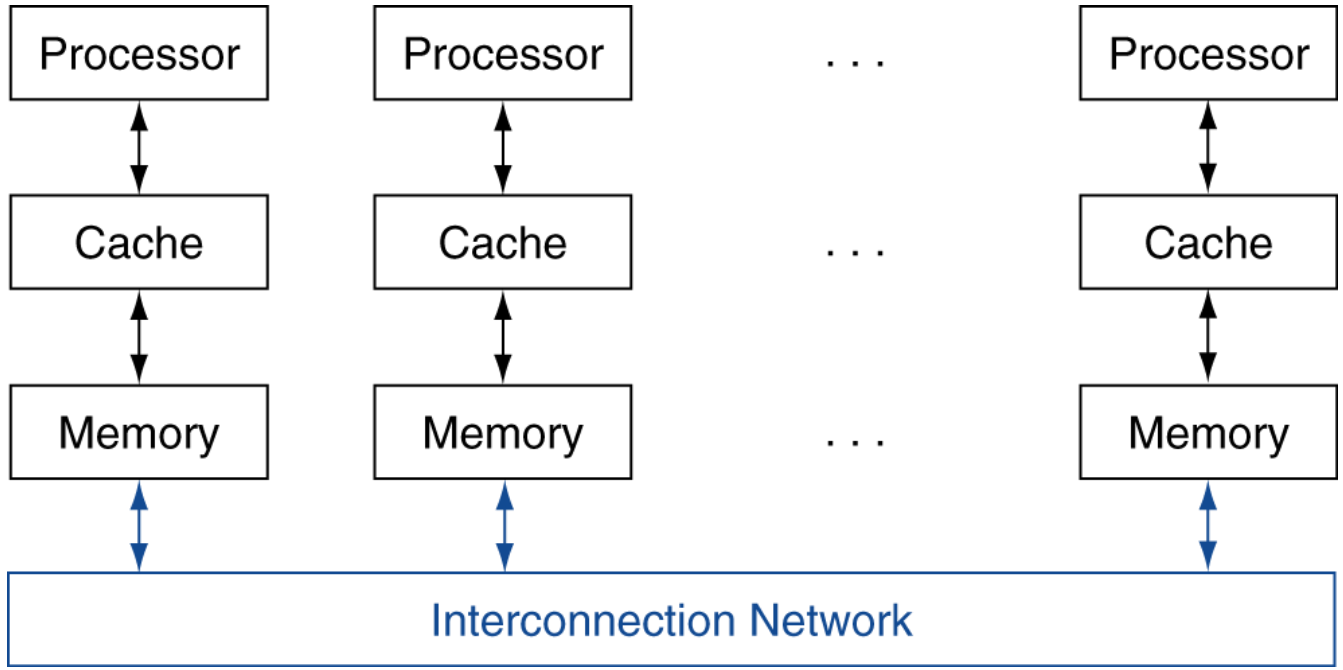


Multithreading Example



Message Passing

- Each processor has private physical address space
- Hardware sends/receives messages between processors



Synchronization: Basic Building Blocks

- Atomic exchange
  - Swaps register with memory location
- Test-and-set
  - Sets under condition
- Fetch-and-increment
  - Reads original value from memory and increments it in memory
- Requires read and write in uninterruptable instruction
- RISC-V: load reserved/store conditional
  - If the memory location specified by the load is changed before the store conditional to the same address, the store conditional fails

Any Questions?

```
            .text
__start:    addi t1, zero, 0x18
            addi t2, zero, 0x21
cycle:      beq t1, t2, done
            slt t0, t1, t2
            bne t0, zero, if_less
            nop
            sub t1, t1, t2
            j cycle
            nop
if_less:    sub t2, t2, t1
            j cycle
done:       add t3, t1, zero
```
